Test paragraph from SSIT section:

Each candidate wave has a certain likelihood p of being interpreted as an IED by a rater, which we express on the logit scale $z = \log(p/(1-p))$; note that z can be positive or negative. The rater's mental processes add noise (uncertainty) n to z, producing a noisy impression, $z' = z + n$. The rater finally applies a threshold θ to reach a decision.

The model has two parameters for each rater: the noise/uncertainty level σ, which reflects a rater's skill in recognizing IEDs (an ideal rater would have a noise level of 0), and the threshold θ, which represents the rater's personal preference as an over- or under-caller.

Estimated internal noise levels σ and threshold θ for experts (blue), experienced non-experts (green), and novices (red) are shown in Figure 4A. As shown in Table 2, the novice group has larger noise/uncertainty $\sigma = 2.664$ [1.724, 8.577]) values compared to experienced non-experts $\sigma = 1.541$ [1.346, 1.838], and experts $\sigma = 1.262$ [1.061, 1.575].
